Objective: Concentrations of cortisol in hair, a novel marker of longer-term cortisol status, were compared in depressed versus nondepressed patients with coronary artery disease (CAD).

Methods: 20 mg hair samples of 3 cm length were collected from 121 patients attending a cardiac rehabilitation program, 34 of whom suffered from depressive symptoms.

Results: Controlling for age, gender, coronary artery bypass grafting, history of depression, and time since most recent acute coronary syndrome, cortisol concentrations ($P = 0.162$) did not predict severity of depression. Younger age ($P = 0.003$) was a significant predictor of depressive symptoms. Perceived stress was not associated with long-term cortisol concentrations ($P = 0.161$).

Conclusions: Cortisol concentrations in hair do not predict depressive symptoms in CAD patients attending cardiac rehabilitation.

Keywords: cortisol, depression, hair, coronary artery disease

Introduction

The prevalence of depression in the general population ranges from 4.4% to 20%, but the prevalence in patients with coronary artery disease (CAD) is at least 2-fold higher.¹⁻³ About 20% of patients with CAD suffer from major depression (MD) within 1 year following an acute coronary syndrome (ACS) while another 27% do not meet diagnostic criteria but show depressive symptoms or suffer from minor depression.⁴⁻⁶ In those with CAD, depressive comorbidity is associated with an increased risk of mortality and medical morbidity independent of traditional cardiac risk factors,⁷⁻¹⁰ and can significantly affect recovery after a major ACS.^{11,12} Depression also has a negative impact on rehabilitation outcomes such as medication adherence,¹³ cardiopulmonary fitness,^{14,15} psychosocial rehabilitation,^{16,17} and overall quality of life.⁹ Moreover, clinical studies of depression in CAD patients show poor response rates and residual symptoms following treatment with selective serotonin reuptake inhibitors.^{18,19} Understanding the etiology of depression associated with CAD is therefore of clinical importance.

It has been shown that depressive symptoms and psychological stress tend to decline over the course of cardiac rehabilitation in concert with an increase in quality of life, while cardiac risk factor profiles improve concurrently, reducing mortality and morbidity.²⁰⁻²⁵ However, symptoms may persist in many patients with depression. Studies have shown that 95% of patients with untreated MD following myocardial infarction (MI) will remain depressed at six months, and up to 70% will remain depressed at 1 year.^{2,26} The reasons why only some patients remain chronically depressed are not understood.

High concentrations of cortisol, the main steroid hormone associated with the stress response system, have been detected in patients with depression.^{27–30} Ongoing elevations have also been associated with risk factors for CAD, including high blood pressure, elevated heart rate, higher waist-to-hip ratio, insulin resistance, diabetes, elevated total and LDL cholesterol, and decreased HDL cholesterol.^{31–33} The relationship between cortisol and depression may be particularly important in CAD patients, because elevated concentrations of cortisol due to hypothalamic-pituitary-adrenal (HPA) axis hyperactivity may be associated with an increased risk of mortality and medical comorbidity.^{31,34–36} Ongoing activation of the HPA axis and high concentrations of cortisol may also be important in the persistence of depressive symptoms.

Typically, concentrations of cortisol in the bloodstream are subject to diurnal variation. Normally, cortisol concentrations peak in the morning and subside in the evening, with the lowest concentrations occurring around midnight.^{37,38} However, in depressed patients this pattern is disrupted and, instead, cortisol peaks earlier in the morning and decreases less in the evening, resulting in increased systemic cortisol exposure.³⁹

Previously, cortisol measurements in saliva, plasma, and urine, have shown short-term changes in the hormone over a period of up to 24 hours.^{40,41} These methods are validated measures of acute stress, but they are subject to the normal diurnal variation in cortisol secretion, and are easily affected by temporary or transient disturbances in psychosocial stress on the day of measurement. Biopsychosocial stressors associated with CAD, however, are likely to be chronic. Therefore, in order to better understand the association between cortisol levels and depression in CAD, long-term measurement of cortisol may be more appropriate, necessitating multiple blood, saliva, or urine samples.⁴²

Recently, a new method has been developed to measure cortisol in hair samples. Because hair grows at a rate of about 1 cm per month, hair cortisol concentrations may provide a long-term measure of cortisol, thereby obviating the need for frequent sampling.⁴³ This method has been validated and shown to be significantly correlated with 24-hour urinary cortisol, therefore having an ability to be used as a biomarker for long-term measurements.⁴³ This method has also been validated in a postpartum sample where hair cortisol was shown to capture the known increased production of cortisol during the third trimester.⁴⁴ The relationship between stress and elevated levels of cortisol in hair has also been shown. In a study by Van Uum et al in patients with chronic pain, hair cortisol was higher in patients with major chronic pain.⁴⁵ Moreover, in a recent study, hair cortisol measurements were

done in patients with Cushing's syndrome, and results indicated that hair cortisol levels were significantly higher than that in healthy controls.⁴⁶

The objective of this study was to investigate the relationship between depressive symptoms and long-term hair concentrations of cortisol in CAD patients.

Methods

Subjects and setting

This was a cross-sectional study of sequentially recruited subjects attending the Toronto Rehabilitation Institute Cardiac Rehabilitation and Secondary Prevention Program (TRI-Cardiac). All experiments on human subjects were conducted in accordance with the Declaration of Helsinki.⁴⁷ All participants gave written informed consent before inclusion in the study. This study was approved by the local Research Ethics Boards. Demographic details and medical history were obtained by electronic chart review.

CAD subjects were identified based on a history of MI, coronary angiographic evidence of $\geq 50\%$ blockage in at least one major coronary artery, or prior revascularization, such as percutaneous coronary intervention (PCI) procedures or coronary artery bypass graft (CABG) surgery at the time of enrolment at the TRI-Cardiac. All CAD patients had entered cardiac rehabilitation a minimum of 6–8 weeks post-CABG (6 weeks for uncomplicated CABG), a minimum of 6 weeks post-MI, or a minimum of 3 weeks post-PCI. TRI-Cardiac involves a 1-year exercise program consisting of both aerobic and resistance training in a group setting with supervision by exercise and medical specialists. Patients were excluded if they had a significant acute medical illness such as cancer, Parkinson's disease, or multiple sclerosis, if a premorbid psychiatric diagnosis of schizophrenia or bipolar disorder was present, or if they had significant cognitive impairment.

Patients were recruited either at entry into the rehabilitation program or at the time of completion of the program after one year to coincide with aerobic testing.

Diagnosis of depression

Depression was diagnosed based on patient history and on a structured clinical interview for depression according to the Diagnostic and Statistical Manual of Mental Disorders version IV (DSM-IV-TR) performed at the time of cortisol sampling.^{48,49} Criteria for diagnosing a major depression included either depressed mood or anhedonia, in combination with changes in appetite and/or weight, insomnia or hypersomnia, agitation or retardation, fatigue or loss of energy,

feelings of worthlessness or guilt, diminished ability to think or being indecisive, or current thoughts of own death. Subjects satisfying 5 of 9 criterion symptoms for 2 weeks, including either sadness or anhedonia, were diagnosed as having MD. Subjects were diagnosed with minor depression if they satisfied 3 criteria, 1 of which was sadness or anhedonia. The presence of a personal or family history of depression was also collected from the subjects.

Severity of depressive symptoms was measured using the Center for Epidemiological Studies Depression Scale (CES-D),⁵⁰ a 20-item depression inventory scored from 0 (least depressed) to 60 (most depressed). This scale has been used extensively in CAD populations.^{15,51}

Stress measurement

Long-term subjective stress was measured using the Perceived Stress Scale (PSS),⁵² a 10-item self-report instrument scored from 0 to 40 that gauges psychological stress responses within the past month. The survey items are short and easy to understand, and this scale has been used widely to investigate relationships with cortisol.⁵³ Time since most recent ACS was also documented as a source of stress and was controlled for in analyses.

Hair samples

A 20 mg hair sample, 3 cm in length (as a measure of average cortisol over the previous 3-month period), was collected by study personnel. All samples were collected from the vertex posterior as close to the scalp as possible using fine-tipped surgical scissors as per our standard protocol. It has previously been demonstrated that cortisol concentrations are not affected by natural hair color nor by dyeing of the hair.^{43,45,53}

Cortisol assays

Each sample was weighed and minced finely with scissors. Afterwards, 1 mL of methanol was added, and the suspension was sonicated for 30 minutes and then incubated overnight for 16 hours at 52°C. After incubation, the methanol was removed from each sample and placed in a glass tube and evaporated in a dry bath under a stream of nitrogen gas. Upon evaporation of methanol, 250 µL of phosphate-buffered saline solution at pH 8.0 was added to the sample and vortexed until well mixed.⁴³ Cortisol measurement was performed using the salivary enzyme-linked immunosorbent assay cortisol kit (Alpco Diagnostics, New Hampshire, US). The extracts were run on the assay according to the instructions from the manufacturer.⁴³ Patients with cortisol concentrations over 1500 ng/g were excluded because these levels are suggestive

of Cushing's syndrome or contamination by cream containing hydrocortisone.⁵⁴

Statistical analysis

Continuous variables were summarized using independent samples t-tests and reported as means \pm SD, whereas categorical measures were summarized using chi-square tests and report as counts and percentages.

The association between cortisol and depression as a categorical variable was assessed using analysis of covariance (ANCOVA). Given that there were 34 patients in the "depressed" cohort, only 4 variables could be used in the model, ie, history of depression, marital status, and age in addition to cortisol. This selection was based on strength of association with depression (see Table 1), and minimal multicollinearity.

Linear regression was performed between depressive symptoms as a continuous variable, using CES-D scores, and cortisol, with covariates of interest such as age, gender, marital status, and time since most recent ACS. Linear regression was also used to assess the association between stress, as measured by PSS scores as a continuous variable, and concentrations of cortisol, with covariates of interest such as age, gender, marital status, and time since most recent ACS in CAD patients.

Since both the presence of depression and depression severity were assessed as primary outcomes, the Bonferroni correction was used in all analyses. Significance was set at $P < 0.025$ (0.05/2).

Hair cortisol concentrations were not normally distributed among patients and were transformed to a logarithmic scale for all analyses.

Results

Subjects

Of 246 patients attending cardiac rehabilitation who were approached for participation, 141 CAD patients were recruited. Fourteen patients were excluded because they had insufficient hair for analysis. One hundred and twenty-seven patients provided hair samples that were analyzed for cortisol concentration. Of these patients, 6 were excluded because their hair cortisol concentration was higher than 1500 ng/g.⁵⁴ Therefore, 121 CAD patients were included in this study. Of these, 34 were depressed and 87 were not depressed (see Figure 1). The sociodemographic characteristics of these patients are summarized in the Table 1.

As expected, mean CES-D scores were significantly higher in depressed patients compared with nondepressed patients ($F = 27.9$, degrees of freedom [DF] = 118, $P < 0.0005$), as were

Table 1 Patient characteristics (n = 121)

mean PSS scores ($F = 1.81$, $df = 118$, $P < 0.0005$). In addition, there were trends for depressed patients to be slightly younger, unmarried, and female, and significantly greater proportions of depressed patients were taking anxiolytics (see Table 1).

Assay results

All collected hair samples were of adequate weight for analysis of cortisol. Hair color and hair dye data were collected from 83 of 121 samples; among these 34 were grey, 14 white, 14 black, 18 brown, and 3 blonde hair samples. The log-transformed mean hair cortisol concentration among the samples that had applied hair dye ($n = 5$) and the ones who have not been treated with dye ($n = 78$) was not significantly different (4.77 ± 0.70 versus 4.95 ± 0.57 , $F = 0.49$, $df = 81$, $P = 0.49$). The log-transformed mean cortisol concentration for nondepressed patients ($n = 87$) was 5.04 ± 0.59 , and

**Figure 1** Flow chart of recruitment process.

Abbreviations: CAD, coronary artery disease; TRI, Toronto Rehabilitation Institute Cardiac Rehabilitation and Secondary Prevention Program (TRI-Cardiac).

for depressed patients ($n = 34$) was 4.96 ± 0.58 , and the values were not significantly different ($F = 0.393$, $df = 119$, $P = 0.53$). Mean cortisol concentrations were not different between patients assessed at baseline or at completion of rehabilitation ($P = 0.109$, $F = 0.260$, $df = 119$).

Hair cortisol and depression

There was no significant difference in the concentration of hair cortisol between depressed and nondepressed patients ($P = 0.825$) in an ANCOVA controlling for age, marital status, and history of depression. Marital status ($P = 0.021$) and history of depression ($P = 0.008$) remained in the final model as the only variables significantly predictive of depression ($\chi^2 = 13.26$, $R^2 = 0.172$, $P = 0.001$). Gender, time since most recent ACS, and CABG were excluded from the ANCOVA based on a lower strength of association (see Table 1).

In a linear regression model predicting severity of depressive symptoms as measured by CES-D scores, including concentrations of cortisol, age, gender, marital status, and time since most recent ACS, cortisol was not associated with CES-D scores ($\beta = -0.148$, $P = 0.162$). Gender ($\beta = 0.042$, $P = 0.678$), marital status ($\beta = 0.021$, $P = 0.837$), CABG ($\beta = -0.035$, $P = 0.747$), and time since most recent ACS ($\beta = 0.019$, $P = 0.846$) were also removed from the model. In the final model, younger age ($\beta = -0.274$, $P = 0.003$) was significantly associated with CES-D scores ($R^2 = 0.088$, $P = 0.004$, $F = 5.86$, $df = 101$), and personal history of depression trended towards significance ($\beta = -183$, $P = 0.059$).

In a linear regression model predicting perceived stress, including cortisol concentration, age, gender, marital status, CABG, history of depression, and time since most recent ACS, cortisol was not associated with PSS scores ($\beta = -0.149$, $P = 0.161$). Gender ($\beta = 0.124$, $P = 0.226$), marital status ($\beta = -0.080$, $P = 0.438$), history of depression ($\beta = -0.006$, $P = 0.957$), time since most recent ACS ($\beta = -0.004$, $P = 0.965$), and CABG ($\beta = -0.057$, $P = 0.597$) were also not significantly associated with PSS scores. In the final model, only younger age ($\beta = -0.245$, $P = 0.013$) was associated with PSS scores ($R^2 = 0.051$, $P = 0.013$, $F = 6.41$, $df = 101$).

There were no differences in average concentration of cortisol between married versus single participants ($P = 0.7$, $F = 0.18$, $df = 119$), males versus females ($P = 0.9$, $F = 1.1$, $df = 119$), those with major or minor depression ($P = 0.6$, $F = 0.88$, $df = 31$), those recruited at entry or at their final visit ($P = 0.094$, $F = 2.850$, $df = 120$), those on or off anxiolytic medications ($P = 0.3$, $F = 0.24$, $df = 119$), or those with a history of depression ($P = 0.17$, $F = 2.81$, $df = 101$).

There were differences in average concentration of cortisol between those who had CABG and those who did not ($P = 0.002$, $F = 1.04$, $df = 119$). This suggests that a stressful intervention, such as a CABG, has significant effects on cortisol levels. Another putative source of stress, ie, angina, did not have significant effects on total cortisol levels ($P = 0.642$, $F = 0.075$, $df = 119$).

Discussion

The present study found no association between long-term concentrations of cortisol and depression or perceived stress in CAD patients. Single marital status and a positive history of depression were found to be significant predictors of the presence of depression, as has been found before.⁵⁵ Similarly, cortisol did not predict severity of depressive symptoms or perceived stress, and only younger age⁵⁶ was associated with both of these. This study utilized a novel method, cortisol deposition in hair, to measure longer-term HPA axis activity. Examination of long-term cortisol concentration in hair is an important complement to other methods which determine short-term changes in cortisol concentrations.

A positive association has previously been documented between depression and acute cortisol measurements.^{57,58} Otte et al found an association between 24-hour urinary cortisol and depression in outpatients with coronary heart disease.⁵⁷ Similarly, Bhattacharyya et al reported an impaired diurnal pattern of cortisol secretion with flatter cortisol rhythms during the day in CAD patients with depression.⁵⁸ Thus, the results from this study using longer-term measurement contrast with those of shorter-term cortisol measurement in CAD. However, in a recent study by Whooley et al 24-hour urinary cortisol had no significant role in explaining the association between depressive symptoms and adverse cardiovascular events.⁵⁹

Our findings may reflect widespread cortisol concentration elevations in our population, as has been seen before.⁶⁰ Mean concentrations of cortisol in both our groups of patients appear higher compared with concentrations of hair cortisol measured in healthy young subjects.⁵⁴ The higher average cortisol concentrations in both depressed and nondepressed CAD patients may reflect the ubiquitous presence of cardiovascular risk factors such as hypertension, diabetes, and obesity, which may be inherently associated with HPA axis dysregulation.^{32,61,62} In addition, all of our CAD patients suffered from a significant event that may have led to ongoing psychosocial stress, another factor that can increase cortisol concentrations in hair.^{45,53} While having a recent ACS may also be associated with increased cortisol,⁶⁰ time since ACS was not significantly associated with cortisol concentrations,

or perceived stress, suggesting that these elevations persist. The resulting chronic cortisol changes would then make it impossible to distinguish between depressed and nondepressed patients using this measure.

Several factors should be considered in interpreting these results. Some participants were receiving concomitant psychotropic medications. In general, there was a low rate of antidepressant use among depressed patients in our population, making it unlikely that antidepressant use affected the results. Similarly, hair cortisol concentrations did not differ in those taking or not taking anxiolytics. The sample size of depressed patients was also relatively small, and comprised both those with major and minor depression. However, there were no differences in hair cortisol concentration in those with major versus minor depression. Also, given the complete lack of a trend for differences between depressed and nondepressed groups, power is not a relevant issue here.

We found that those with depressive symptoms had higher mean PSS scores. This, and the fact that those with depressive symptoms had more use of anxiolytics, suggests comorbid anxiety. Anxiety was not directly investigated in this study. Because anxiety and depression commonly co-occur and the presence of anxiety may stimulate the HPA axis,⁶³ anxiety might be an important cofactor in this population. State and trait anxiety should be evaluated in conjunction with depression and stress in future studies to better understand this relationship.

It would also be interesting to compare hair cortisol concentrations in this group of patients with healthy age-matched controls, and those with MD but no CAD. Long-term cortisol in hair has not been measured in solely depressed subjects or in different types of depression, including melancholic and nonmelancholic. As a result, it is not clear whether the method has the sensitivity to detect changes in HPA axis functioning that would be typical of those found in MD. An additional limitation of this study is that it is unknown how long depressive episodes lasted prior to collection of the hair sample. Finally, medical history was ascertained by chart review, and patients were not specifically questioned about somatic diseases such as thyroid dysfunction,⁶⁴ which could disrupt HPA axis function and lead to altered cortisol levels.

Conclusion

This study found no association between chronically elevated concentrations of cortisol and depression or stress in CAD patients attending rehabilitation. Known demographic covariates such as marital status, age, and history of depression were significant predictors, and none of these are targets for intervention. Depression is a significant problem

in CAD patients and the biologic factors that may mediate this comorbidity remain largely unknown. Further research investigating the relationship between depression and CAD is warranted.

Neuropsychiatric Disease and Treatment

Dovepress

Publish your work in this journal

Neuropsychiatric Disease and Treatment is an international, peer-reviewed journal of clinical therapeutics and pharmacology focusing on concise rapid reporting of clinical or pre-clinical studies on a range of neuropsychiatric and neurological disorders. This journal is indexed on PubMed Central, the 'PsycINFO' database and CAS, and is the official

journal of The International Neuropsychiatric Association (INA). The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
